HYDROGEN DEGRADATION OF PRE-OXIDIZED ZIRCONIUM ALLOYS

ABSTRACT

The presence of the oxide layers on Zr alloys may retard or enhance the hydrogen entry and material degradation, depending on the layer features. This research has been aimed to determine the effects of pre-oxidation of the Zircaloy-2 alloy at a different temperature on hydrogen degradation. The specimens were oxidised in laboratory air at 350°C, 700°C, and 900°C. After, some samples were tensed at 10⁻⁵ strain rate and simultaneously charged with hydrogen under constant direct voltage in 1 N sulfuric acid at room temperature. Other specimens were charged without any tension, then annealed at 400°C for 4 h and finally tensed at above strain rate. The SEM examinations were performed on the cross-sections and fracture faces of specimens. The obtained results demonstrate the effects of the oxide layer on the cathodic current and hydrogen entry, mechanical properties and the appearance of hydrides and fracture behaviour.

Keywords: *zirconium alloys, oxidation, hydrogen degradation, slow strain rate tests, cathodic hydrogen charging*

INTRODUCTION

Background

Zirconium alloys are widely used in chemical and nuclear industries because of their excellent mechanical and corrosion properties, and their low neutron absorption under operational conditions. They are applied as fuel cladding tubes and other structural elements in light water reactors [1]. The zirconium alloys used in nuclear industry include Zr-Sn and Zr-Nb alloys. The nuclear accidents such as loss of coolant accident (LOCA) and reactivity initiated accidents (RIA) may result in degradation of fuel claddings associated with hydrogen appearance, entry into the metal and its degradation. The excessive oxidation at high temperatures can cause the breakaway of the oxide layer and formation of the easy hydrogen diffusion channels [1,2]. Both phenomena are related to each other by the manner not fully recognized by now.

Oxidation

The oxidation process takes place through two steps and layers. Like the first, a layer of dense tetragonal β -zirconia is formed and then it transforms progressively to an fcc α -zirconia external layer [3]. The transformation temperature depends on an alloy composition and oxidizing environment. The oxide films fabricated hydrothermally on Zr alloys may have monoclinic ZrO_2 structure even at 200°C after 24 h of treatment [4]. In another research on the Zircaloy-4, the monoclinic and the tetragonal phases were formed already at 350°C temperature [5]. At temperatures of 950–1200°C both crystallographic structures of an oxide phase may be still present [6]. Both phases may then appear at moderate temperatures.

The layer oxide was observed to compose of two zones, the outer one being porous, the inner one more dense and defective [4]. The sub-stoichiometric zirconium oxide captured the oxygen atoms from near stoichiometric tin oxides or niobium oxides, and the reduction of tin ions caused the protection loss of the inner layer. The oxide layer was observed to be microcrystalline, growing into columnar grains [7]. The mean crystallite size increased at increasing oxide thickness. The more complex layer structure at a different stage of oxidation was also reported [8]; the interface exhibited an intermediate ZrO layer, a discontinuous layer of “blocky” Zr_3O grains embedded in the ZrO layer, and a suboxide layer appeared being an oxygen saturated solid solution in the metal matrix. A protective oxide layer according to [9] is composed of monoclinic ZrO_2 and a small amount of tetragonal $\text{ZrO}_{1.88}$, which acts as a very effective diffusion barrier.

The destabilization of the oxide layer may occur by a different mechanism: cracking of the oxide resulting from the transformation of tetragonal to the monoclinic structure (breakaway phenomenon); cracking of the oxide as a result of the accumulation of compressive stresses followed the volume expansion attendant upon oxide formation; porosity formed in the oxide. The appearance of breakaway oxidation depends on temperature, environment and alloy composition. The breakaway oxidation in steam (without nitrogen) occurs at temperatures up to 1300K [10] and after time ranged between 2400 and 5500 s [6]. In other research on the same alloy, the oxide layer was indeed compact at 1200°C, even if the oxide scale formed at 1000°C indicated breakaway phenomena [11]. Oxides grown on pure zirconium were less permeable than those on multiphase alloys because of a greater number of grain boundaries, interfaces and diffusion pathways [12]. Significant differences between the alloys were found in the temperature range 870–1320K, and the breakaway of Zircaloy-4 was reported to be significant at 1000°C and above [13].

The oxidation in air is strongly influenced by the breakaway effect, as the nitrogen diffusion through cracks to the metal–oxide interface results in nitride formation [1,13]. The oxide layer may then be degraded by local inclusions of zirconium nitride. Finally, the porosity may increase breaking up the coherent microstructure of the oxide scale and result again in the oxide breakaway. These effects become important under conditions of oxygen starvation. The inclusions showed a tendency for nitrogen to displace some oxygen atoms within the oxide layer, degrading the oxide scale integrity and promoting further oxidation [10]. Oxygen can be then considered as an active species and nitrogen as a catalyst that promotes breakaway [14]. Formation of the zirconium nitride phase in the oxide near the metal-oxide boundary increased up to 1473/1573K [1]. A mixed ZrO_2/ZrN zone in the samples was seen at 973 and 1073K for Zircaloy-4, resulting in very porous and thick oxide scales. However, at 1673K, Zircaloy-4 exhibited a dense oxide scale and no evidence of formation of ZrN at the metal-oxide boundary.

Pre-oxidation retards or even prevents the attack of nitrogen and, hence, leads to slower oxidation kinetics in the air compared to tests without pre-oxidation. As long as the oxide

scale is dense, no transport of nitrogen to the metal is possible. Only after formation of cracks nitrogen may contribute to the degradation phenomenon, but the acceleration of the reaction is delayed compared to that for no pre-oxidized alloy [1]. However, in the tests performed in the MOZART facility [15], pre-oxidation at low temperatures made faster the breakaway oxidation in air. In the quench test, the pre-oxide and absorbed hydrogen did not affect the high-temperature oxidation [16]. In comparison with steam, chemical heat release during oxidation in the air was higher by 80%, which may lead to a more rapid escalation of the nuclear accident. The barrier effect of the cladding against the release of fission products was presumed to be lost earlier in the air compared to steam [1].

Hydrogen degradation

Hydrogen may appear in zirconium alloys in an interstitial solution of zirconium, hydrogen bonded by weak (dislocations, vacancies, O atoms) or strong traps (interfaces of inclusions), and as hydrides. The interstitial solubility is strongly dependent on temperature and ranges between 50 ppm at room temperature to even 50 wt pct at 1000-1300K [18]. Maximum hydrogen contents of H/Zr=0.9 were obtained for the lowest temperatures, and highest partial pressures investigated [19]. The diffusivity of H in Zr equals to $5.468 \cdot 10^{-7} \exp(-45293/RT) \text{ m}^2/\text{s}$ [20]. The previous hydrogen solubility and diffusion data are a little diverse [21].

Two stable hydride phases, δ -hydride (fcc) and ϵ -hydride (fct), and at least one metastable phase, γ -hydride (fct) may appear at different temperature and hydrogen content [22]. The δ -hydride phase was found to be the predominant at hydrogen content up to 1250 wt ppm, at about 3000 wt ppm of hydrogen a significant amount of γ -hydride was observed, and at the highest hydrogen content, over 6000 wt ppm, the ϵ -hydride phase appeared [23]. The hydrides observed in fuel cladding exposed to reactor environment were the most often fcc δ -hydride $\text{ZrH}_{1.6}$ [7]. The intergranular hydrides had a stronger effect on ductility than the intragranular ones [24]. At high cooling rates or large matrix grains, a predominance of intragranular hydrides was observed, while lower cooling rates or small grain sizes produced more intergranular or grain boundary hydrides. The macro-hydride orientation was significantly influenced by applied stresses; compressive forces reoriented hydrides with their normal perpendicular to the loading direction [25].

The Zr alloys are either strengthened or softened by hydrogen, depending on temperature and hydrogen content [26]. Hydrides as reported in [25] always degraded the tensile strength, ductility and fracture toughness. The softening can be attributed to the interstitial hydrogen solution [27]. The Young's modulus and the shear modulus of the zirconium hydrogen solid solution decreased with increasing hydrogen content. The microhardness of solid zirconium solution was reduced by hydrogen addition [28]. The ductility of solid zirconium solution increased with hydrogen addition. In [29] the elongation and ductility were reported to decrease significantly with increasing hydrogen content, but the room temperature strength slightly increased. The hydrogen-reduced the fracture toughness [7]. The fracture strains decreased rapidly with increasing hydride blister/layer depth to levels of about 100 μm deep and then remained roughly constant [30]. As the hydrogen content increased, an increase in the strength, a decrease in the ductility and the maximum stress were observed with increasing hydrogen content for Zircaloy-4 [31]. The ductility at room temperature decreased with increasing hydrogen content [26]. The room temperature strength of Zr-Sn-Fe-Nb tubes increased slightly, and the ductility decreased with the formation of the hydrides [32]. The loss of ductility in the presence of circumferential hydrides was associated with the secondary cracking during the final process of the fracture. When studying the Zr-Nb tubes charged

with hydrogen at elevated temperature and quenched, the ultimate tensile stresses and plastic elongations decreased drastically when the cooling rate was reduced [33]. Hydrogen concentration had a weak effect on mechanical characteristics in comparison to the temperature influence; only fracture stress for hydrogen containing specimens was considerably higher, and the modulus of elasticity increased in the range of 20–200°C [34].

The fracture behavior was also dependent on the presence of hydrides. The solid solution H atoms resulted in a ductile fracture, on the contrary to ZrH₂ precipitate [35]. The as-received (non-oxidized) samples were completely plastic, and they deformed without cracking in the ring compression test. For the specimen containing 220 ppm H, at 25°C, almost completely brittle behavior was observed [36]. A dimple fracture was normally seen in the as-received specimens, whereas some cracks across the zirconium matrix appeared at 300 wt ppm of hydrogen. In the case of the 700 ppm charged specimen, a brittle fracture was a dominating mechanism with secondary cracks found on the fracture surface. Such secondary cracks along the platelets of hydrides were also observed on the fracture surfaces of tubes [32]. In [27], the cleavage facets were observed on the fracture surface of unalloyed Zr and a mixture of dimple and cleavage facets for the Nb-containing alloys. At the grain size below 30 μm, the cracks were small and independent, while above 500 μm they became larger and propagated along the radial direction. Not only large cracks but also small bulges were observed [37]. The ductile fracture showed some dimples associated with ductile metallic ligaments [17]. However, in another research, except for some specimens with high H concentration at room temperature, the macroscopic fracture behaviour was ductile [38]. For specimens possessing the circumferential hydrides, the fracture was ductile. Transverse fracture of the circumferential hydrides produced a much smaller fractured area than the lengthwise fracture of the radial hydrides under the tensile hoop stress state [33].

The hydrogen degradation mechanism is still discussed. Hydrogen-induced decohesion was considered as the main mechanism explaining the loss of ductility at medium and high hydrogen contents. Cracks can easily propagate through the hydrides between two Zr atomic layers [39]. Hydrogen-induced decohesion and the volume misfit between the Zr and hydride phases can create the sufficient stress for fracture. In [40], the hydrogen-induced embrittlement of the hcp Zr matrix was not confirmed, and hydrogen fracture in the presence of hydrides was attributed to the brittle nature of hydrides. The hydride presence was also postulated [41] to create a hydrogen concentration gradient, where the bulk concentration was greater than that at the crack tip. This concentration gradient was considered as the driving force for diffusion of hydrogen to the crack tip and subsequent hydride growth. Predominantly grain boundary hydrides were observed. According to [35], hydrogen atoms at low contents could help in dislocation multiplication, following the hydrogen-enhanced localized plasticity mechanism. At high contents, the dislocations and cracks could nucleate from precipitate - matrix interface, indicating the decohesion mechanism as a primary method for Zr degradation.

Oxides and hydrogen entry

There is few data on hydrogen solubility and diffusion in the oxide layers. The hydrogen dissolution in monoclinic ZrO oxide at 500–1100°C temperatures in oxygen/water vapor atmosphere ranged from 10⁻⁵ to 10⁻⁴ mol H/mol oxide and decreased with increasing temperature [42]. The hydrogen uptake in the initial phase controlled by hydrogen diffusion through the growing oxide layer was proportional to $t^{3/8}$ [43]. Hydrogen content in alloys oxidized at high dissolved oxygen (DO) conditions was invariably lower than that obtained at low DO conditions [44].

The perfect oxide itself presents an effective barrier to the absorption of hydrogen. An initially high hydrogen absorption rate may decrease with increasing oxide thickness up to the oxide phase transition region [7]. Enrichment of hydrogen along oxide boundaries together with porosity networks around particles and oxide interfaces were observed. The pores were local reduction sites where H_2 evolved on transition metal sites [45]. In [46] the effect of pre-charging on oxidation was investigated. The hydrogen-charged specimens of 200 ppm and 450 ppm were oxidized for ~60 days at 360°C and 17.5 MPa under the water atmosphere. These oxidized hydrogen-charged specimens were found to contain respective hydrogen concentrations of 250 ± 25 ppm and 500 ± 25 ppm, indicating the further hydrogen pickup during the oxidation process.

During and after the transition, the concentration of hydrogen may strongly depend on the presence of cracks in the oxide layers, formed by the breakaway phenomenon. The cracks within the oxide layer could enhance the oxygen and hydrogen movements through the oxide layer [6]. In such cracks, hydrogen was strongly enriched [47]. At small protective oxide thickness, a fraction of absorbed hydrogen increased with exposure time, then reached a plateau, started to increase again reaching a peak and decreased [48].

There is neither agreed hydrogen diffusion mechanism through the oxide layer nor known data about the hydrogen diffusion coefficient within the oxide [49]. A presence of oxygen may affect hydrogen migration barriers on an atomic scale. Hydrogen can be trapped by oxygen atoms positioned along the preferred path. It means that the trajectory will deviate from a straight line. Secondly, migration barriers for hydrogen between two octahedral interstitials increase when an oxygen atom is present in the neighboring interstitial; migration enthalpy is about 0.6 eV in the absence of oxygen and 0.9 V in its presence [50].

The oxygen dissolved in the metal considerably decreased the hydrogen absorption capacity of zirconium [19]. The O–H bond may appear in the oxide layer, and such trapping can prevent hydrogen diffusion. An oxide layer of 20 μm in thickness was formed on the surface of zirconium hydride after hydrogen desorption in the presence of oxygen [9]. A loose zone with holes and cracks appeared on the top of the oxide layer, and a dense and compact layer - on the zirconium hydride. Such oxide layers can change the hydrogen desorption behaviour because they constitute the efficient diffusion barriers on the surface of zirconium hydride.

The nanoscale pores are also introduced by the alloying elements that have a low solid solubility in the α -Zr matrix and display faster diffusion of their cations in ZrO_2 than Zr^{4+} . The oxide porosity provides then short circuits for oxygen and hydrogen diffusion [51].

Aim

So far research has made excellent progress in the recognition of oxidation process, its determinants, the structure of the oxide layers. Similar progress has been observed for hydrogen uptake and diffusion, and an appearance of hydrogen delayed cracking and hydrogen-enhanced creep. However, no such knowledge has been obtained for a role of oxide layers in hydrogen absorption by the metal, which can determine the later hydrogen degradation. Therefore this paper is aimed to determine.

MATERIAL AND METHODS

The Zircaloy-2 alloy (Sn 1.36%, Fe 0.18%, Cr 0.11%, Ni 0.07%, C 0.013%, Si 0.091%, Al 0.023%, others < 0.01, Zr rem.) delivered by Areva, was investigated. The smooth specimens for slow strain rate tests were cut in the transverse direction to the rolling direction. The specimens had dimensions 120 mm of total length, 50 mm of the length of working part and 4 mm of thickness. The surface preparation was developed based on such far reports, in which different procedures were proposed, from the grinding with the No. 1,200 paper [37] to the paper No. 5,000 and diamond paste 0.5 μm [4]. In this research, the specimens were polished with abrasive papers, No. 2,000 as the last, and diamond paste of 3 μm of granulation, and then cleaned in distilled water in an ultrasonic bath and dried in warm air.

Afterwards, the specimens were put in the electric oven and heated for 30 min. in laboratory air. The heating temperature was maintained at 350°C, 700°C and 900°C. The first temperature corresponds to the normal working conditions of zirconium pellets; the others approach the conditions of the LOCA nuclear accident. The specimens were put in the oven already heated to the above temperatures and after the oxidation removed and cooled in laboratory air.

Then the specimens were charged with hydrogen. The hydrogenation can be performed by different ways: with gaseous hydrogen at elevated temperature [52-55], with gaseous hydrogen by Sievert's apparatus [38,56,57] or with electrolytic hydrogen at room temperature in H_2SO_4 [16,21,58,59] or in KOH [17,38,60] or at elevated temperature [12]. The cathodic charging with hydrogen at room temperature was chosen as the suitable for simultaneous, in some experiments, slow strain rate tests. The cathodic current density 80 mA/cm^2 was here used as the highest value, by some previous tests [21,58]. The imposed voltage was varied from 2 to 30 V to try to force the current flow between two electrodes, Pt and Zr alloy in oxidised and no oxidised specimens.

The specimens were subjected to slow strain rate test at 10^{-5} s^{-1} strain rate in 1M H_2SO_4 at ambient temperature. The tests were made with the specially designed and constructed equipment. The force and elongation were monitored during the tensile tests.

In the first series of experiments, the specimens were simultaneously charged and tensed. In the second series, the specimens were oxidized in the same way and afterwards charged with hydrogen without any load at 80 mA/cm^2 for 72 h. Then they removed from the solution, cleaned with distilled water and annealed for 4 h at 400°C, following earlier reports [17,32,56,58,60], to obtain the bulk distribution of hydrogen inside the whole specimen. The specimens were put in the oven already heated to the above temperature and after annealing cooled with the oven. The heated specimens were then tensed at the same charging conditions. Both series were made to compare the effects of surface and bulk hydrogen.

The microscopic examinations of the specimens were performed with the JEOL 7800 F scanning electron microscope on the cross-sections of polished specimens before any test (reference specimens), after oxidation and after hydrogen charging. The etching of cross-sections was made with the solution containing 45 cm^3 of 65% HNO_3 , 10 cm^3 of 40% HF and 45 cm^3 of distilled water. After tension, similar examinations were performed on fracture faces to determine the presence and distribution of hydrides, and the mechanism and path of failure.

RESULTS

The structure of the alloy before an oxidation is shown in Fig. 1. The significant number of intermetallic $Zr_2(Ni, Fe)$ and $Zr(Cr, Fe)_2$ precipitates dispersed in the matrix, is seen.

The surfaces of specimens oxidized at 350°C and 700°C were smooth and homogenous; only some cracks appeared on surfaces of the last specimens. On the contrary, the surface of specimen oxidized at 900°C showed the signs of an early breakaway of likely an upper zone of the oxide layer (the details were discussed in [61]).

The cross-sections of some oxide layers obtained at elevated temperatures are shown in Fig. 3. The increasing oxidation temperature causes an increase in layer thickness, from some nanometers for non-oxidised alloy through about 10 µm after the oxidation at 700°C to about 25 µm after the oxidation at 900°C for 0.5 h.

Fig. 1. The cross-sections of the as-received Zircaloy-2 alloy (different magnification)

Fig. 2. View of surfaces of the specimen oxidized at 900°C for 0.5 h

Fig. 3. Cross-sections of the oxide layers a) after oxidation at 700°C for 0.5 h, b) after oxidation at 900°C for 0.5 h. The green lines show the oxide thickness

The stress - strain curves are demonstrated in Fig. 4 for both non-oxidized (reference) and oxidized and hydrogen charged in different conditions specimens. The hydrogen charging has a small and complex effect on tensile properties. The specimens tensed and charged simultaneously demonstrate the highest tensile strength and those charged, annealed and tensed – a little smaller tensile strength and similar elongation. The no-charged specimens have the comparable tensile strength and the smallest elongation. The oxidation at 900°C causes an apparent decrease in plasticity.

Fig. 4. Stress – strain curves for specimens oxidized at 350°C, and charged with hydrogen during SSRT or charged, annealed and tensed, and for reference specimens. The cathodic current density, charging time, temperature and time of annealing, are shown

The cross-sections of some oxidized at 350°C and hydrogen charged specimens are shown in Fig. 5 for the specimens simultaneously charged and tensed, and the specimens charged, heated at 400°C and then tensed. The first specimens demonstrate the microstructure similar to no-charged specimens, even close to the oxide – matrix boundary (not shown here). On the contrary, on specimens tensed after hydrogen charging and annealing the lines of cracks caused by the hydrides are long about 100 μm and randomly distributed in the matrix, and branched.

Fig. 5. The cross-sections of specimens oxidized at 350°C and: a, b) simultaneously hydrogen charged at 80 mA/cm² and tensed; c, d) hydrogen charged at 80 mA/cm² for 72 h, heated at 400°C for 4 h and then tensed

The cross-sections of the alloy oxidized at 700°C and hydrogen charged specimens are shown in Fig. 6 for the specimens simultaneously charged and tensed and the specimens charged, heated at 400°C and then tensed. Some small cracks, up to a few micrometers in length, are visible at higher magnifications.

Fig. 6. The cross-sections of specimens oxidized at 700°C, hydrogen charged at 80 mA/cm² for 72 h, heated at 400°C for 4 h and then tensed, at different magnifications and different area of the specimen

The fracture faces after oxidation at 350°C and hydrogen charging are shown in Fig. 7 for the specimens simultaneously charged and tensed, and the specimens hydrogen charged, annealed at 400°C and then tensed. The ductile transgranular fracture is observed for the first specimens and similar fracture with likely both intergranular and transgranular cracks for the second group of specimens.

Fig. 7. The fracture faces of the specimens oxidized at 350°C and: a, b) simultaneously hydrogen charged at 80 mA/cm² and tensed; c, d) hydrogen charged at 80 mA/cm² for 72 h, heated at 400°C for 4 h and then tensed

The fracture faces after oxidation at 700°C and hydrogen charging are shown in Fig. 8 for the hydrogen charged specimen, annealed at 400°C and then tensed. The ductile transgranular fracture is always observed with very short cracks.

Fig. 8. The fracture faces of the specimens oxidized at 700°C, hydrogen charged at 80 mA/cm² for 72 h, heated at 400°C for 4 h and then tensed

Table 1 demonstrates the effect of oxidation time on cathodic charging parameters under constant voltage conditions. The increase in oxidation temperature from 350°C to 700°C results in a drastic decrease in cathodic current, and from 350°C to 900°C – in fall of the current to zero.

Table 1. Cathodic charging parameters

| Oxidation temperature | Cathodic current density | Cathodic voltage | Charging time |
|-----------------------|----------------------------|------------------|---------------|
| 350°C/30 min. | 80 mA/cm ² | 3 V to 2 V | 72 h |
| 700°C/30 min. | 20 – 40 mA/cm ² | 10 V | 72 h |
| 900°C/30 min. | 0 | 30 V | 72 h |

The mean hydrogen content, for the specimens oxidized at 350°C, hydrogen charged at 80 mA/cm² for 72 h, annealed at 400°C for 6 h and then tensed, equals 73.9 ± 14.1 wt. ppm. For specimens oxidized at higher temperatures, the hydrogen content is about 15 ppm, within the limits of experimental error.

DISCUSSION

One might assume that at the thin oxide layer hydrogen can enter the metal and at imposed high current/voltage parameters the hydrides can form at the oxide/metal interface. It is to note that the hydrogen amount was in each test sufficient to form hydrides. However, we did not observe any hydrides in nonannealed specimens; they likely appeared in a very thin zone close to the interface because of a low hydrogen diffusion coefficient, D_H , about 10^{-7} to 10^{-10} cm²/s, according to various researchers [62].

During our standard charging time 72 h, hydrogen can diffuse for distance:

$$x = (D t)^{1/2} \quad (1)$$

For $D_H = 10^{-7}$ cm²/s, the distance is about 1610 μm, and for $D_H = 10^{-10}$ cm²/s, it is 50.9 μm. As we have not observed any hydrides near the oxide - matrix interface at high magnification on the cross - sections, the hydrogen diffusion coefficient seems close rather to the second value or even be lower. Both values have been calculated from an extrapolation of high-temperature data, and it is possible that the hydrogen coefficient value at low temperatures deviates from that predicted by the Arrhenius law because of hydrogen trapping.

During annealing at 400°C, the approximate values of D_H can be as reported between 10^{-5} to 10^{-8} cm²/s. Based on the above Fick equation, the distances of hydrogen migration are between 0.509 mm and 1.61 cm. The microscopic examinations show, however, that the distribution of hydrides is regular and on the whole surface so that the applied annealing conditions have been adequate and the hydrogen diffusion coefficient is closer rather to the higher of above values.

The effects of hydrogen on stress-strain curves in such conditions are of minor importance. The only distinct loss of elongation after oxidation at 900°C is likely originated from grain recrystallization at this high temperature as no hydrogen can enter the specimen at zero current value. The hydrogen absorption seems to result in moderate softening, likely by interstitial hydrogen. The results are by some earlier reports [27,28]. The effects of interstitial hydrogen and hydride phases are opposite, but the distinct loss of plasticity observed in another studies [25,26,29,31] might appear at high hydrogen content and a great number of hydrides. The separation of these effects is not easy at low hydrogen content.

The slow strain rate tests have been never made for simultaneously tensed and hydrogen charged Zr alloys. For many metallic materials, the slow strain rate tests in the corrosive or hydrogen-containing environment have shown the initiation of cracks on the surface and their significant progress during tensile tests. Such behaviour has been considered as due to the hydrogen screening of dislocations, a decrease of their mutual interaction and movement of dislocations at lower flow stress, i.e. local softening of material at macroscopically brittle fracture known as the Hydrogen Enhanced Localised Plasticity (HELP). The lack of such effect for specimens nonoxidized and oxidized at 350°C is evidence that this mechanism may be unable to cause the movement and multiplication of dislocations. Thus the propagation of cracks even at low hydrogen content may occur via Hydrogen Enhanced Decohesion as sometimes suggested in the past [35], likely because of very low interstitial hydrogen content at low temperature. At high temperatures, on the other hand, the dislocations cannot be pinned by hydrogen atoms.

When, at the same conditions, the annealing has been performed after charging, we have observed the appearance of branched hydrides. However, the cracking mechanism changed only a little: the metal fractured by ductile mechanism and in a transgranular way. The cleavage or quasi-cleavage fracture could be observed only at the hydride – matrix interface.

The effect of the oxide layer is the most important finding. The presence of 10 µm oxide layer after the oxidation at 700°C causes the apparent decrease in current value. Such oxide layer is still stable and shows neither the breakaway effect nor a presence of cracks penetrating through the oxides. One might say that the oxide layer is permeable to hydrogen atoms, but the hydrogen diffusion at room temperature through this layer is very low.

The effect of oxidation at 900°C is surprising. Even after annealing at 400°C for 6 h, the zero current is observed, then the hydrogen atoms are unable to cross over the 25 µm oxide layer during 72 h of charging. A comparison of both effects makes it possible to assess the diffusion rate of hydrogen within the oxide layer from the equation (1):

$$(10 \times 10^{-4})^2 / 2.59 \times 10^{-5} < D_{H/ox} < (25 \times 10^{-4})^2 / 2.59 \times 10^{-5}$$
$$3.86 \times 10^{-12} \text{ cm}^2/\text{s} < D_{H/ox} < 2.41 \times 10^{-11} \text{ cm}^2/\text{s}$$

So far there has been known no data on the hydrogen diffusion coefficient in the zirconium oxide, and this result is the first. Even if it is indirect value, it is very reasonable and explains why the presence of continuous oxide layer may be very important for prevention of hydrogen entry into the zirconium pellets.

It is symptomatic that the above effects are observed even at substantial breakaway of the zirconia layer after oxidation at 900°C. The breakaway is limited only to the outer oxide layer, with the inner oxide layer still compact and well adjacent to the base. In earlier research, no such positive effect of pre-oxidation has been observed [46]. Despite that, based on present results we assume that the pre-oxidation may to some extent prevent the hydrogen entry and degradation during the LOCA nuclear accident. Our next tests will be performed to assess how the oxidation temperature and time may affect the barrier effect on zirconium alloys.

The most important safety condition for nuclear power plants is the reliability of nuclear reactors. The maintenance properties may then depend, among others, on thickness, continuity (lack of cracks), adhesion and morphology of the oxide layer, determining the resistance to hydrogen degradation of fuel claddings. The present research may indicate, after further detailed verification with other parameters, alloys, and environments, the surface modification method of zirconium fuel pellets as improving their behaviour in conditions of the LOCA nuclear accident.

CONCLUSIONS

Hydrogen, in an amount below 100 wt. ppm has a moderate effect on stress-strain curves. The hydrogen absorption seems to result in moderate softening, likely by interstitial hydrogen. The appearance of hydrides results in branched cracks initiating at and propagating from hydride – matrix interfaces.

The presence of 10 µm oxide layer after the oxidation at 700°C causes the apparent decrease in current value and hydrogen entry, and after the oxidation at 900°C results in no hydrogen absorption even in the presence of the breakaway phenomenon. The oxide layer is permeable to hydrogen atoms, but the hydrogen diffusion at room temperature through this layer seems very low.

The measurements of cathodic current at different thickness of oxide layer gives a possibility to calculate the hydrogen diffusion coefficient $D_{H/ox}$ within the oxide layer. Based on that, the $D_{H/ox}$ is estimated as being between $3.86 \times 10^{-12} \text{ cm}^2/\text{s}$ and $2.41 \times 10^{-11} \text{ cm}^2/\text{s}$.

The present results suggest that pre-oxidation may to some extent prevent the hydrogen entry and degradation during the LOCA nuclear accident. The verification of this assumption should be made in particular for higher test temperature and vapor environment.
